TRUST-TECH-Based Expectation Maximization for Learning Finite Mixture Models

Chandan K. Reddy, Member, IEEE, Hsiao-Dong Chiang, Fellow, IEEE, and Bala Rajaratnam

Abstract—The Expectation Maximization (EM) algorithm is widely used for learning finite mixture models despite its greedy nature. Most popular model-based clustering techniques might yield poor clusters if the parameters are not initialized properly. To reduce the sensitivity of initial points, a novel algorithm for learning mixture models from multivariate data is introduced in this paper. The proposed algorithm takes advantage of TRUST-TECH (TRansformation Under STability-reTaining Equilibria CHaracterization) to compute neighborhood local maxima on the likelihood surface using stability regions. Basically, our method coalesces the advantages of the traditional EM with that of the dynamic and geometric characteristics of the stability regions of the corresponding nonlinear dynamical system of the log-likelihood function. Two phases, namely, the EM phase and the stability region phase, are repeated alternatively in the parameter space to achieve local maxima with improved likelihood values. The EM phase obtains the local maximum of the likelihood function and the stability region phase helps to escape out of the local maximum by moving toward the neighboring stability regions. Though applied to Gaussian mixtures in this paper, our technique can be easily generalized to any other parametric finite mixture model. The algorithm has been tested on both synthetic and real data sets and the improvements in the performance compared to other approaches are demonstrated. The robustness with respect to initialization is also illustrated experimentally.

1 INTRODUCTION

In the field of statistical pattern recognition, finite mixtures allow a probabilistic model-based approach to unsupervised learning [20]. One of the most popular methods used for fitting mixture models to the observed data is the Expectation Maximization (EM) algorithm, which converges to the maximum likelihood estimate (MLE) of the mixture parameters locally [7], [27]. The traditional steepest descent, conjugate gradient, or Newton-Raphson methods are too complicated for use in solving this problem [39]. EM has become a popular method since it takes advantage of some problem specific properties. EM-based methods have been successfully applied to solve a wide range of problems that arise in pattern recognition [2], [3], clustering [1], information retrieval [22], computer vision [5], data mining [32], etc.

In this paper, we consider the problem of learning the parameters of Gaussian Mixture Models (GMMs). Fig. 1 shows data generated by three Gaussian components with different means and variances. Note that every data point has a probabilistic (soft) membership that gives the probability with which it belongs to each of the components. The data points that belong to component 1 will have a high probability of membership for component 1. On the other hand, data points belonging to components 2 and 3 are not well separated. The problem of learning mixture models involves not only estimating the parameters of these components but also finding the probabilities with which each data point belongs to these components. Given the number of components and an initial set of parameters, the EM algorithm can be applied to compute the optimal estimates of the parameters that maximize the likelihood function. However, the main problem with the EM algorithm is that it is a “greedy” method that converges to a local maxima on the log-likelihood surface. Hence, the final solution that the EM algorithm converges to will be very sensitive to the given initial set of parameters.

This local maxima problem (popularly known as the initialization problem) is one of the well-studied issues in the context of the EM algorithm. Several algorithms have been proposed in the literature to solve this issue. To overcome this problem, we propose a novel three-phase algorithm based on stability region analysis [24]. The main research concerns that motivated the new algorithm presented in this paper are as follows:

- The EM algorithm for mixture modeling converges to a local maximum of the likelihood function very quickly.
- There are many other promising local optimal solutions in the close vicinity of the solutions obtained from the methods that provide good initial guesses of the solution.
- Model selection criteria usually assumes that the global optimal solution of the log-likelihood function can be obtained. However, achieving this is computationally intractable.
the work and discusses future research directions.

Section 4 describes our new framework, along with the details of our implementation and the complexity.

Section 3 discusses some preliminaries about mixture models, the EM algorithm, and stability regions. Although EM and its variants have been extensively used for learning mixture models, several researchers have approached the problem by identifying new techniques that give good initialization. More generic techniques like deterministic annealing [31], [35] and genetic algorithms [23], [17] have been applied to obtain a good set of parameters. Although these techniques have asymptotic guarantees, they are very time consuming and, hence, cannot be used in most practical applications. Some problem specific algorithms like split and merge EM [36], component-wise EM [9], greedy learning [37], incremental version for sparse representations [21], and parameter space grid [15] have also been proposed in the literature. Some of these algorithms are either computationally very expensive or infeasible when learning mixture models in high-dimensional spaces [15]. In spite of the high computational cost associated with these methods, very little effort has been made to explore promising subspaces within the larger parameter space. Most of these algorithms eventually apply the EM algorithm to move to a locally maximal set of parameters on the likelihood surface. Simpler practical approaches like running EM from several random initializations and then choosing the final estimate that leads to the local maximum with the highest value of the likelihood have also been successful to a certain extent [12], [30].

Even though some of these methods apply other additional mechanisms (like perturbations [8]) to escape out of the local optimal solutions, systematic methods are yet to be developed for searching the subspace. The dynamical system of the log-likelihood function reveals more information on the neighborhood stability regions and their corresponding local maxima [6]. Hence, the difficulties in finding good solutions when the error surface is very rugged can be overcome by adding stability region-based mechanisms to escape out of the convergence zone of the local maxima. Although this method might introduce some additional cost, one has to realize that the existing approaches are much more expensive due to their stochastic nature. There appears to be a minor similarity between our method and some of the approaches available in the literature [36], [9], [37] in terms of moving to different basins of attraction in the neighborhood of the current local maximum. In fact, some of these methods [36], [37] change the number of components in this process of searching for different regions. The main distinction of our work is the use of the theory of stability regions to develop an efficient computational method that can search for neighborhood local maxima.

For a problem of this nature where there is a nonuniform distribution of local maxima, it is difficult for most of the methods to search neighboring regions [40]. For this reason, it is more desirable to apply the TRUST-TECH-based Expectation Maximization (TT-EM) algorithm after obtaining some point in a promising region. The main advantages of the proposed algorithm are that it

- explores most of the neighborhood local optimal solutions unlike traditional stochastic algorithms,
- acts as a flexible interface between the EM algorithm and other global methods,
- allows the user to work with existing clusters obtained from other standard approaches and improves the quality of the solutions based on the maximum likelihood criteria,
- helps in truncating some of the expensive global methods during their early stages, and
- exploits the fact that promising solutions are obtained by faster convergence of the EM algorithm.

The rest of this paper is organized as follows: Section 2 gives some relevant background about various methods proposed in the literature for solving the problem of learning mixture models. Section 3 discusses some preliminaries about mixture models, the EM algorithm, and stability regions. Section 4 describes our new framework, along with the details of our implementation and the complexity. Section 5 shows the experimental results of our algorithm on synthetic and real data sets. Finally, Section 6 concludes the work and discusses future research directions.

### 2 Relevant Background

Although EM and its variants have been extensively used for learning mixture models, several researchers have approached the problem by identifying new techniques that give good initialization. More generic techniques like deterministic annealing [31], [35] and genetic algorithms [23], [17] have been applied to obtain a good set of parameters. Although these techniques have asymptotic guarantees, they are very time consuming and, hence, cannot be used in most practical applications. Some
3 Preliminaries

We now introduce some necessary preliminaries on mixture models, the EM algorithm, and stability regions. First, we describe the notation used in the rest of the paper (Table 1).

### 3.1 Mixture Models

Let us assume that there are $k$ Gaussian components in the mixture model. The form of the probability density function is as follows:

$$p(x|\Theta) = \sum_{i=1}^{k} \alpha_i p(x|\theta_i),$$

where $x = [x_1, x_2, \ldots, x_d]^T$ is the feature vector of $d$ dimensions. Throughout this paper, bold notation indicates that it is a vector quantity unless otherwise explicitly stated. The $\alpha_i$s represent the mixing weights. The symbol $\Theta$ represents the parameter set $(\alpha_1, \alpha_2, \ldots, \alpha_k, \theta_1, \theta_2, \ldots, \theta_k)$ and $p$ is a d-variate Gaussian density parameterized by $\theta_i$ (that is, $\mu_i$ and $\Sigma_i$):

$$p(x|\theta_i) = \frac{|\Sigma_i|^{-\frac{1}{2}}}{(2\pi)^{\frac{d}{2}}} e^{\frac{1}{2}(x-\mu_i)^T \Sigma_i^{-1}(x-\mu_i)}.$$  

It should also be noticed that, being probabilities, $\alpha_i$ must satisfy

$$0 \leq \alpha_i \leq 1, \ \forall i = 1, \ldots, k, \ \text{and} \ \sum_{i=1}^{k} \alpha_i = 1.$$  

Given a set of $n$ independent and identically distributed (i.i.d.) samples $\mathcal{X} = \{x^{(1)}, x^{(2)}, \ldots, x^{(n)}\}$, the log-likelihood corresponding to a mixture is

$$\log p(\mathcal{X}|\Theta) = \log \prod_{j=1}^{n} p(x^{(j)}|\Theta)$$

$$= \sum_{j=1}^{n} \log \sum_{i=1}^{k} \alpha_i p(x^{(j)}|\theta_i).$$

The goal of learning mixture models is to obtain the parameters $\hat{\Theta}$ from a set of $n$ data points that are samples from a distribution with density given by (1). The MLE is given by

$$\hat{\Theta}_{MLE} = \arg \max_{\Theta} \{ \log p(\mathcal{X}|\Theta) \},$$

where $\Theta$ indicates the entire parameter space. Since this MLE cannot be found analytically for mixture models, one has to rely on iterative procedures that can find the global maximum of $\log p(\mathcal{X}|\Theta)$. The EM algorithm described in the next section has been successfully used to find the local maximum of such a function [18].

### 3.2 EM

The EM algorithm considers $\mathcal{X}$ to be observed data. The missing part, termed hidden data, is a set of $n$ labels $\mathcal{Z} = \{z^{(1)}, z^{(2)}, \ldots, z^{(n)}\}$ associated with $n$ samples, indicating that component which produced each data point [18]. Each label $z^{(j)} = [z_i^{(j)}, z_2^{(j)}, \ldots, z_k^{(j)}]$ is a binary vector, where $z_i^{(j)} = 1$ and $z_i^{(j)} = 0 \forall i \neq i$ means the sample $x^{(j)}$ was produced by the $i$th component. Now, the complete log-likelihood, that is, the one from which we would estimate $\Theta$ if the complete data $\mathcal{Y} = \{\mathcal{X}, \mathcal{Z}\}$ were known, is

$$\log p(\mathcal{X}, \mathcal{Z}|\Theta) = \sum_{j=1}^{n} \log \prod_{i=1}^{k} \alpha_i p(x^{(j)}|\theta_i)^{z_i^{(j)}},$$

$$\log p(\mathcal{Y}|\Theta) = \sum_{j=1}^{n} \sum_{i=1}^{k} z_i^{(j)} \log [\alpha_i p(x^{(j)}|\theta_i)].$$

The EM algorithm produces a sequence of estimates $\{\hat{\Theta}(t), t = 0, 1, 2, \ldots\}$ by alternately applying the following two steps until convergence:

- **E-Step.** Compute the conditional expectation of the hidden data, given $\mathcal{X}$ and the current estimate $\hat{\Theta}(t)$. Since $\log p(\mathcal{X}, \mathcal{Z}|\Theta)$ is linear with respect to the missing data $\mathcal{Z}$, we simply have to compute the conditional expectation $\mathcal{W} = E[Z|\mathcal{X}, \hat{\Theta}(t)]$ and plug it into $\log p(\mathcal{X}|\hat{\Theta}(t))$. This gives the Q-function as follows:

$$Q(\Theta|\hat{\Theta}(t)) = E_{\mathcal{Z}}[\log p(\mathcal{X}, \mathcal{Z})|\mathcal{X}, \hat{\Theta}(t)].$$

Since $\mathcal{Z}$ is a binary vector, its conditional expectation is given by

$$w_i^{(j)} = E[Z_i^{(j)}|\mathcal{X}, \hat{\Theta}(t)]$$

$$= P[Z_i^{(j)} = 1|\mathcal{X}^{(j)}, \hat{\Theta}(t)]$$

$$= \frac{\alpha_i p(x^{(j)}|\theta_i)}{\sum_{i=1}^{k} \alpha_i p(x^{(j)}|\theta_i)},$$

where the last equality follows from the Bayes law ($\alpha_i$ is the a priori probability that $z_i^{(j)} = 1$, whereas $w_i^{(j)}$ is the posteriori probability that $z_i^{(j)} = 1$ given the observation $x^{(j)}$).

- **M-Step.** The estimates of the new parameters are updated using the following equation:

$$\hat{\Theta}(t+1) = \arg \max_{\Theta} \{Q(\Theta, \hat{\Theta}(t))\}.$$
3.3 EM for GMMs

Several variants of the EM algorithm have been extensively used to solve this problem. The convergence properties of the EM algorithm for Gaussian mixtures are thoroughly discussed in [39]. The Q-function for GMM is given by

\[
Q(\Theta|\hat{\Theta}(t)) = \sum_{j=1}^{n} \sum_{k=1}^{K} w_i^j \left[ \log \left( \frac{\left| \Sigma_k \right|}{\left| \Sigma \right|} \right) - \frac{1}{2} (x(j) - \mu_j)^T \Sigma_k^{-1} (x(j) - \mu_j) + \log \alpha_k \right],
\]

where

\[
w_i^j = \frac{\tilde{\alpha}_i(t) \tilde{\Sigma}_i(t)}{\sum_{i=1}^{K} \tilde{\alpha}_i(t) \tilde{\Sigma}_i(t)} e^{-\frac{1}{2} (x(j) - \tilde{\mu}_i(t))^T \tilde{\Sigma}_i(t)^{-1} (x(j) - \tilde{\mu}_i(t))}.
\]

The maximization step is given by the following equation:

\[
\frac{\partial}{\partial \Theta} Q(\Theta|\hat{\Theta}(t)) = 0,
\]

where \(\Theta_k\) is the parameters for the \(k\)th component. Because the posterior probabilities in the E-step now appear in the Q-function as given constants and, therefore, resemble the Gaussian likelihood when the components are prespecified, maximizing this function in the M-step becomes trivial. The updates for the maximization step in the case of GMMs are given as follows:

\[
\mu_k(t + 1) = \frac{\sum_{j=1}^{n} w_i^j x(j)}{\sum_{j=1}^{n} w_i^j},
\]

\[
\Sigma_k(t + 1) = \frac{\sum_{j=1}^{n} w_i^j (x(j) - \mu_k(t + 1))(x(j) - \mu_k(t + 1))^T}{\sum_{j=1}^{n} w_i^j},
\]

\[
\alpha_k(t + 1) = \frac{1}{n} \sum_{j=1}^{n} w_i^j.
\]

3.4 Stability Regions

This section mainly deals with the transformation of the original log-likelihood function into its corresponding nonlinear dynamical system and introduces some terminology pertinent to comprehend our algorithm. Let us denote the number of unknown parameters as \(s\). This transformation gives the correspondence between all of the critical points of the \(s\)-dimensional likelihood surface and that of its dynamical system. For the case of a simple spherical Gaussian mixture with \(k\) components, we have \(s = 3k - 1\). It should be noted that only \((k - 1)\) \(\alpha\) values are considered in the gradient system because of the unity constraint. The dependent variable \(\alpha_k\) is written as follows:

\[
\alpha_k = 1 - \sum_{j=1}^{k-1} \alpha_j.
\]

For the case of a general full covariance \(d\)-variate Gaussian mixture with \(k\) components, contribution to \(s\) stems from the \(kd\) parameters through the component means \(\mu_j\), \(\frac{1}{2} kd(d + 1)\) parameters through the \(k\) covariances \(\Sigma_k\), and the \(k - 1\) mixing weights \(\alpha_j\). Altogether, \(s\) is therefore given by \(s = kd + \frac{1}{2} kd(d + 1) + (k - 1) = k \left[ \frac{1}{2} (d + 1)(d + 2) \right] - 1\). For convenience, the maximization problem is transformed into a minimization problem as follows:

\[
\max_{\Theta} \{ \log p(X|\Theta) \} = \min_{\Theta} \{ -\log p(X|\Theta) \} = \min_{\Theta} f(\Theta).
\]

In our construction of the dynamical system corresponding to the \(s\)-dimensional likelihood surface, we require that \(f(\Theta)\) be twice continuously differentiable. The following simple lemma asserts this result.

**Lemma 1.** \(f(\Theta)\) is \(C^2(\mathbb{R}^s, \mathbb{R})\).

**Proof.** Note from (4) that we have

\[
f(\Theta) = -\log p(X|\Theta) = -\sum_{j=1}^{n} \log \sum_{i=1}^{K} \alpha_i p(x(j)|\theta_i)
\]

\[
= -\sum_{j=1}^{n} \log \sum_{i=1}^{K} \left[ \frac{\left| \Sigma_i \right|}{\left| \Sigma \right|} \right] e^{-\frac{1}{2} (x(j) - \mu_i)^T \Sigma_i^{-1} (x(j) - \mu_i)}.
\]

Each of the simple functions which appear in (17) are twice differentiable and continuous in the interior of the domain over which \(f(\Theta)\) is defined (in fact, they are infinitely differentiable). The function \(f(\Theta)\) is composed of arithmetic operations of these simple functions and, from the basic results in the analysis, we can conclude that \(f(\Theta)\) is twice continuously differentiable. \(\square\)

**Definition 1.** \(\hat{\Theta}\) is said to be a critical point of (16) if it satisfies the following condition:

\[
\nabla f(\Theta) = 0.
\]

A critical point is said to be nondegenerate if, at the critical point \(\hat{\Theta} \in \mathbb{R}^s\), \(d^T \nabla^2 f(\Theta) d \neq 0 \quad (\forall d \neq 0)\). We construct the following gradient system in order to locate critical points of the objective function (16):

\[
\dot{\hat{\Theta}}(t) = F(\Theta) = -\nabla f(\Theta),
\]

where the state vector \(\Theta\) belongs to the euclidean space \(\mathbb{R}^s\) and the vector field \(F : \mathbb{R}^s \rightarrow \mathbb{R}^s\) satisfies the sufficient condition for the existence and uniqueness of the solutions. The solution curve of (19) starting from \(\Theta\) at time \(t = 0\) is called a trajectory and it is denoted by \(\Phi(\Theta, \cdot) : \mathbb{R} \rightarrow \mathbb{R}^s\). A state vector \(\Theta\) is called an equilibrium point of (19) if \(F(\Theta) = 0\). An equilibrium point is said to be hyperbolic if the Jacobian of \(F\) at point \(\hat{\Theta}\) has no eigenvalues with zero real part.

Lemma 1 and the preceding arguments guarantee the existence of the gradient system associated with \(f(\Theta)\) and allow us to construct the following dynamical system:

\[
\dot{\Theta}(t) = \left[ \frac{\partial f}{\partial \mu_1} \cdots \frac{\partial f}{\partial \mu_k} \frac{\partial f}{\partial \sigma_1} \cdots \frac{\partial f}{\partial \sigma_{kd+1}} \frac{\partial f}{\partial \alpha_1} \cdots \frac{\partial f}{\partial \alpha_{k-1}} \right]^T.
\]
From the implementation point of view, it is not required to define this gradient system. However, to understand the details of our method and its theoretical foundations, it is necessary to obtain this gradient system. This will enable us to define concepts like stable equilibrium point (SEP), stability region, and stability boundary, all of which will be described here briefly. In this paper, we introduce a novel computational technique that uses these concepts and build a few approximations to make this method work well in practice.

**Definition 2.** A hyperbolic equilibrium point is called a (asymptotically) stable equilibrium point (SEP) if all of the eigenvalues of its corresponding Jacobian have negative real part. Conversely, it is an unstable equilibrium point if some eigenvalues have a positive real part.

An equilibrium point is called a type-\( k \) equilibrium point if its corresponding Jacobian has exact \( k \) eigenvalues with positive real part. The stable \((W^s(\tilde{x}))\) and unstable \((W^u(\tilde{x}))\) manifolds of an equilibrium point, say, \( \tilde{x} \), are defined as

\[
W^s(\tilde{x}) = \{ x \in \mathbb{R}^n : \lim_{t \to \infty} \Phi(x,t) = \tilde{x} \},
\]

\[
W^u(\tilde{x}) = \{ x \in \mathbb{R}^n : \lim_{t \to -\infty} \Phi(x,t) = \tilde{x} \}.
\]

The task of finding multiple local maxima on the log-likelihood surface is transformed into the task of finding multiple stable equilibrium points on its corresponding gradient system. The advantage of our approach is that this transformation into the corresponding dynamical system will yield more knowledge about the various dynamic and geometric characteristics of the original surface and leads to the development of a powerful method for finding improved solutions. In this paper, we are particularly interested in the properties of the local maxima and their one-to-one correspondence to the stable equilibrium points. To comprehend the transformation, we need to define the concept of an energy function. A smooth function \( V(\cdot) : \mathbb{R}^n \to \mathbb{R} \) satisfying \( V(\Phi(\Theta,t)) < 0 \), [a vector of zeros], \( \forall x \notin \{ \text{set of equilibrium points} (E) \} \), and \( t \in \mathbb{R}^+ \) is termed as the energy function.

**Theorem 3.1** [6]. \( f(\Theta) \) is an energy function for the gradient system (20).

**Definition 3.** A type-1 equilibrium point \( x_d \) (\( k = 1 \)) on the practical stability boundary of a stable equilibrium point \( x_s \) is called a decomposition point.

Our approach takes advantage of TRUST-TECH (TRansformation Under STability-reTaining Equilibria CHaracterization) to compute neighborhood local maxima on likelihood surface using stability regions. Originally, the basic idea of our algorithm was to find decomposition points on the practical stability boundary. Since each decomposition point connects two local maxima uniquely, it is important to obtain the saddle points from the given local maximum and then move to the next local maximum through this decomposition point [25]. Although this procedure gives a guarantee that the local maximum is not revisited, the computational expense for tracing the stability boundary and identifying the decomposition point is high compared to the cost of applying the EM algorithm directly using the exit point without considering the decomposition point. In a particular direction away from the local maximum, the point where the value of the energy function reaches the maximum is called an exit point \( (x_1, x_2) \) and \( x_3 \) in Fig. 4a). One can use the saddle point tracing procedure described in [25] for applications where the local methods like EM are more expensive.

**Definition 4.** Tier-1 local maximum is a neighborhood local maximum obtained by integrating the gradient system after a small perturbation along the eigenvector direction corresponding to the positive eigenvalue of the Jacobian at the decomposition point on the stability boundary of any given local maximum.

**Definition 5.** The practical stability region of a stable equilibrium point \( x_s \) of a nonlinear dynamical system (19), denoted by \( A_p(x_s) \), is the interior of closure of the stability region \( \Phi(x_s) \), which is given by

\[
A(x_s) = \{ x \in \mathbb{R}^n : \lim_{t \to \infty} \Phi(x,t) = x_s \}.
\]

The boundary of the practical stability region is called the practical stability boundary of \( x_s \) and will be denoted by \( \partial A_p(x_s) \). Theorem 3.2 asserts that the practical stability boundary is contained in the union of the closure of the stable manifolds of all the decomposition points on the practical stability boundary. Hence, if the decomposition points can be identified, then an explicit characterization of the practical stability boundary can be established using (24). This theorem gives an explicit description of the geometrical and dynamical structure of the practical stability boundary.

**Theorem 3.2** (Characterization of practical stability boundary) [14]. Consider a negative gradient system described by (19). Let \( \gamma_i = 1, 2, \ldots \) be the decomposition points on the practical stability boundary \( \partial A_p(x_s) \) of a stable equilibrium point, say, \( x_s \). Then,

\[
\partial A_p(x_s) = \bigcup_{\gamma \in \partial A_p} W^s(\gamma).
\]

Fig. 2 gives an example of a Tier-1 local maximum. The EM algorithm converges to a local maximum \( (LM_i) \). By
tracing the stability boundary, one can find a decomposition point $\gamma$ using the procedure described in [25]. The eigenvector direction corresponding to the positive eigenvalue of the Jacobian evaluated at $\gamma$ will connect two local maxima. Hence, a new local maximum $\gamma_{new}$ can be obtained by following the gradient after perturbing in that eigenvector direction toward the opposite side of the existing local maximum $\gamma_{old}$.

### 3.5 Model Selection Criterion

Another important issue in mixture modeling is the selection of the number of components that is usually unknown in real-world problems. A mixture with too many components will overfit the data, while a mixture with too few components will be too simple to approximate the underlying distribution. Most of the methods available in the literature for model selection add a penalty term in the objective function that can potentially penalize more complex models. A detailed review of different criteria used to penalize complex models is given in [19]. Bayesian approaches are also successful in identifying the number of components [30]. The methods of model selection can be divided into two families. One is based on a random sampling mechanism, for example, Markov Chain Monte Carlo (MCMC) methods [11], [28], [29]. The main disadvantage of these methods is the computational expense in attaining the global optimal solution. The other one is based on some deterministic criteria similar to the minimum message length (MML) criterion [9]. A review of cross validation schemes for mixture modeling can be seen in [33].

We will be able to incorporate any model selection criterion in our method by merely modifying the likelihood function. The proposed method works in the same way as before, except that the likelihood function will have some additional terms. Our method deals with the nonlinearity of the likelihood surface directly and, hence, it is independent of the number of components chosen in the model. In fact, the improvements in the likelihood will be bigger in this case because of the additional terms that create more nonlinearity of the surface. We would like to emphasize that the main focus of our work is to reduce or solve the initialization problem associated with the learning of mixture models and not the automatic selection of the number of components. However, we justify that, using our methodology, we can exploit the maximum potential of the given number of mixture components by trying to find better estimates of the likelihood. In other words, solving the initialization issue will indirectly impact the choice of the number of components.

### 4 TRUST-TECH-BASED ALGORITHM

Our framework consists of three phases. The first phase is the global phase in which the promising solutions in the entire search space are obtained. The second phase is the local phase (or the EM phase), where the promising solutions obtained from the previous phase are refined to the corresponding locally optimal parameter set. The third phase, which is the main contribution of this paper, is the stability region phase. The exit points are computed and the neighborhood solutions are systematically explored through these exit points in this phase. Fig. 3 shows the block diagram of our algorithm. The EM phase and the stability region phase are repeated alternatively in the promising regions of the parameter search space.

This approach can be treated as a hybrid between global methods for initialization and the EM algorithm, which gives the local maxima. One of the main advantages of our approach is that it searches the parameter space more systematically. This approach differs from traditional local methods by computing multiple local solutions in the neighborhood region. This also enhances user flexibility by allowing the users to choose between different sets of good clusterings. Although global methods give promising subspaces, it is important to explore this subspace more thoroughly, especially in problems like this one. Algorithm 1 describes our approach.

Fig. 4 shows the different steps of our algorithm in both the parameter space (Fig. 4a) and the function space (Fig. 4b). In order to escape this local maximum, our method needs to compute certain promising directions based on the local behavior of the function. One can realize that generating these promising directions is one of the important aspects of our algorithm. Surprisingly, choosing random directions to move out of the local maximum works well for this problem. One might also use other directions like eigenvectors of the Hessian or incorporate some domain-specific knowledge (like information about priors, approximate location of cluster means, user preferences on the final clusters, etc.), depending on the application that they are working on and the level of computational expense.
that they can afford. We used random directions in our work because they are very cheap to compute. Once the promising directions are generated, exit points are computed along these directions. Exit points are points of intersection between any given direction and the practical stability boundary of that local maximum along that particular direction. If the stability boundary is not encountered along a given direction, it is very likely that one might not find any new local maximum in that direction. With a new initial guess in the vicinity of the exit points, the EM algorithm is applied again to obtain a new local maximum.

**Algorithm 1 TT_EM Algorithm**

**Input:** Parameters \( \Theta \), Data \( X \), tolerance \( \tau \), Step \( S_p \)

**Output:** \( \hat{\Theta}_{MLE} \)

**Algorithm:**
Apply global method and store the q promising solutions \( \Theta_{init} = \{ \Theta_1, \Theta_2, ..., \Theta_q \} \)
Initialize \( E = \phi \)
while \( \Theta_{init} \neq \phi \) do
  Choose \( \Theta_i \in \Theta_{init} \), set \( \Theta_{init} = \Theta_{init} \setminus \{ \Theta_i \} \)
  \( LM_i = EM(\Theta_i, X, \tau) \)
  \( E = E \cup \{ LM_i \} \)
  Generate promising direction vectors \( d_j \) from \( LM_i \)
  for each \( d_j \) do
    Compute Exit Point \( (X_j) \) along \( d_j \) starting from \( LM_i \)
    by evaluating the log-likelihood function given by (4)
    \( New_j = EM(X_j + \epsilon \cdot d_j, X, \tau) \)
    if \( new_j \notin E \) then
      \( E = E \cup New_j \)
    end if
  end for
end while
\( \hat{\Theta}_{MLE} = \max \{ val(E_i) \} \)

**4.1 Implementation Details**

Our program is implemented in Matlab and runs on a Pentium IV 2.8 GHz machine. The main procedure implemented is TT_EM, described in Algorithm 2. The algorithm takes the mixture data and the initial set of parameters as input, along with step size for moving out and the tolerance for convergence of the EM algorithm. It returns the set of parameters that correspond to the Tier – 1 neighboring local optimal solutions. The procedure \( eval \) returns the log-likelihood score given by (4). The Gen_Dir procedure generates promising directions from the local maximum. Exit points are obtained along these generated directions. The procedure update moves the current parameter to the next parameter set along a given \( k \)th direction \( Dir[k] \). Some of the directions might have one of the following two problems:

1) Exit points might not be obtained in these directions.
2) Even if the exit point is obtained, it might converge to a less promising solution. If the exit points are not found along these directions, the search will be terminated after \( Eval_{MAX} \) number of evaluations. For all exit points that are successfully found, the EM procedure is applied and all of the corresponding neighborhood set of parameters are stored in the \( Params[ ] \). To ensure that the new initial points are in different stability regions, one should move along the directions “\( \epsilon \)” away from the exit points. Because the parameters will be of different ranges, care must be taken while computing the step sizes. It is important to use the current estimates to get an approximation of the step size with which one should move out along each parameter in the search space. Finally, the solution with the highest log-likelihood score among the original set of parameters and the Tier-1 solutions is returned.

**4.2 Complexity of the Algorithm**

We will now analyze the time complexity of the TRUST-TECH-EM algorithm presented in the previous section. An extensive discussion on the rate of convergence of the EM algorithm is available in [7]. This rate depends on the proportion of information available in the observed data. Consider the case of a full covariance \( d \)-variate GMM with \( k \) components and \( n \) data points. Let us summarize the cost of each EM step. The E-step in (9) requires operations of order \( O(nk\lambda) \), where \( \lambda \) is the cost of computing the density
of a multivariate normal at a given point \( p(x^{(j)}|\theta) \). The M-step from (14) requires operations of order \( O(nkd) \) due to the calculation of the component means, of order \( O(nkd^2) \) from calculations of the component covariance matrices and of order \( O(k) \) from calculation of the mixing weights. The computational cost of the EM step for each iteration is therefore of the order \( O(nk\lambda + nkd^2) \). For higher dimensional problems, \( \lambda \) is negligible compared to \( d^2 \) and \( d^2 \approx n \). Hence, the cost of EM will be \( O(n^2) \), which is quadratic in \( n \).

We will now quantify the additional cost incurred due to the stability region phase of the TRUST-TECH method. This phase allows us to escape out of the local maximum and it basically requires the evaluation of the log-likelihood function at several points along a particular direction. The evaluation of the log-likelihood function value during the stability region phase requires \( nkd + 2nk + 2n \) operations (see (4)). Assuming that there are a maximum of \( c \) number of function evaluations (\( Eval_{MAX} \)) along a particular direction, the total complexity of the stability region phase will be \( O(2ckn) \) (since \( k << n \)). This is linear in terms of \( n \). Hence, the stability region phase requires a negligible additional cost compared to the EM phase. Finally, the overall cost of the TRUST-TECH-EM method will be equal to \( O(bn^2) \), where \( b \) is the number of directions chosen. This quantity is the same as the cost of using \( b \) random starts and applying the EM algorithm for each of the starts.

**Algorithm 2** Params[ ] TT_EM(Pset, Data, Tol, Step)

\[
Val = eval(Pset) \\
Dir[ ] = Gen_Dir(Pset) \\
Eval_{MAX} = 500 \\
for k = 1 to size(Dir) do \\
  Params[k] = Pset, ExtPt = OFF \\
  Prev_Val = Val \\
  Cnt = 0 \\
  while (!ExtPt) && (Cnt < Eval_{MAX}) do \\
    Params[k] = update(Params[k], Dir[k], Step) \\
    Cnt = Cnt + 1 \\
    Next_Val = eval(Params[k]) \\
  if (Next_Val > Prev_Val) then \\
    ExtPt = ON \\
  end if \\
  Prev_Val = Next_Val \\
end while \\
if count < Eval_{MAX} then \\
  Params[k] = update(Params[k], Dir[k], ASC) \\
else \\
  Params[k] = EM(Params[k], Data, Tol) \\
end if \\
Return max(eval(Params[ ]))

5 RESULTS AND DISCUSSION

Our algorithm has been tested on both synthetic and real data sets. The initial values for the centers and the covariances were chosen to be uniformly random. Uniform priors were chosen for initializing the components. For real data sets, the centers were chosen randomly from the sample points.

5.1 Results on Synthetic and Real-World Data Sets

A simple synthetic data with 40 samples and 5 spherical Gaussian components was generated and tested with our algorithm. Priors were uniform and the standard deviation was 0.01. The centers for the five components are given as follows: \( \mu_1 = [0.3 \ 0.3]^T, \mu_2 = [0.5 \ 0.5]^T, \mu_3 = [0.7 \ 0.7]^T, \mu_4 = [0.3 \ 0.7]^T, \) and \( \mu_5 = [0.7 \ 0.3]^T \).

The second data set was that of a diagonal covariance case containing \( n = 900 \) data points. The data generated from a two-dimensional three-component Gaussian mixture distribution with mean vectors at \( [0 \ -2]^T, [0 \ 0]^T, [0 \ 2]^T \) and the same diagonal covariance matrix with values 2 and 0.2 along the diagonal [35]. All three mixtures have uniform priors. The true mixtures with data generated from these three components are shown in Fig. 5. The data points appear to be in three well-separated Gaussian clusters.

Fig. 6 shows various stages of our algorithm and demonstrates how the clusters obtained from existing algorithms are improved using our algorithm. The initial clusters obtained are of low quality because of the poor initial set of parameters. Our algorithm takes these clusters and applies the stability region step and the EM step simultaneously to obtain the final result. Fig. 7 shows the value of the log-likelihood during the stability region phase and the EM iterations.

To demonstrate the performance of our algorithm on high-dimensional problems, we extended the elliptical data set to higher dimensions (50, 100, and 200). The centers were generated by simultaneously repeating the following 3-by-2 matrix: [0; rand; rand; 0; rand], and the covariance matrix is obtained by repeating the following 3-by-2 matrix: [200*rand 20*rand; 200*rand 20*rand; 200*rand 20*rand]. Here, rand indicates a uniform random variable between 0 and 1. To improve the running time, we used only 90 data points with uniform mixing weights. The number of search directions \( (=20) \) is a constant in all three cases.

In the third synthetic data set, more complicated overlapping Gaussian mixtures are considered [9]. The para-
meters are as follows: $\mu_1 = \mu_2 = [-4 -4]^T$, $\mu_3 = [2 2]^T$, and $\mu_4 = [-1 -6]^T$. $\alpha_1 = \alpha_2 = \alpha_3 = 0.3$ and $\alpha_4 = 0.1$.

$$\Sigma_1 = \begin{bmatrix} 1 & 0.5 \\ 0.5 & 1 \end{bmatrix}, \quad \Sigma_2 = \begin{bmatrix} 6 & -2 \\ -2 & 6 \end{bmatrix},$$

$$\Sigma_3 = \begin{bmatrix} 2 & -1 \\ -1 & 2 \end{bmatrix}, \quad \Sigma_4 = \begin{bmatrix} 0.125 & 0 \\ 0 & 0.125 \end{bmatrix}.$$ 

Originally, there were 1,000 samples generated, as shown in Fig. 8. However, we have conducted experiments to show the performance improvements of our algorithm by increasing the number of data points.

Two real data sets obtained from the UCI Machine Learning repository [4] were also used for testing the performance of our algorithm. The widely used Iris data with 150 samples, 3 classes, and 4 features was used. The wine data set with 178 samples was also used for testing. The wine data had 3 classes and 13 features. For these real data sets, the class labels were deleted, thus treating it as an unsupervised learning problem. Table 2 summarizes our results over 100 runs. The mean and the standard deviations of the log-likelihood values are reported. The traditional EM algorithm with random starts is compared against our algorithm on both the synthetic and real data sets. Our algorithm not only obtains a higher likelihood value but also produces it with higher confidence. The low standard deviation of our results indicates the robustness of obtaining higher likelihood values. In the case of the wine data, the improvements with our algorithm are not much more significant compared to the other data sets. This might be due to the fact that the data set might not have Gaussian components. Our method assumes that the underlying distribution of the data is a mixture of Gaussians. Finally, the performance of our algorithm on high-dimensional data is also shown. With a fixed number of search directions, the dimensionality of the data is increased and the improvements in the average MLE are shown.

Table 3 gives the results of TRUST-TECH compared with other methods proposed in the literature like split and merge EM and k-means+EM [41]. MRS+EM indicates the multiple random starts experiment, which includes the same number of starts as the number of valid directions in the case of the TRUST-TECH method. The multiple starts are made only in the promising regions. RS+EM is just a single random start and is given here to illustrate the lower bound on the performance of our method empirically.

5.2 Discussion

It will be effective to use our algorithm for those solutions that appear to be promising. Due to the nature of the
problem, it is very likely that the nearby solutions surrounding the existing solution will be more promising. One of the primary advantages of our method is that it can be used along with other popular methods already available and thus improve the quality of existing solutions. In clustering problems, it is an added advantage to perform refinement of the final clusters obtained. As shown in Fig. 6, our algorithm can help in improving the quality of existing clusters. Even in such a simple case, the initial algorithm identified only one of the three clusters correctly. Our algorithm used the existing solution and identified three distinct clusters that are identical to the true mixtures. Most of the focus in the literature has been on new methods for initialization or new clustering techniques, which often do not take advantage of the existing results and completely start the clustering procedure "from scratch." Though shown only for the case of multivariate Gaussian mixtures, our technique can be effectively applied to any parametric finite mixture model.

A closer examination of that in Table 2 indicates that, for the high-dimensional examples (Elliptical 50, 100, 200), the variance does not necessarily go up with increasing dimensionality. This might be due to the limited number of initial starts and the associated inherent inability to explore vast higher dimensional spaces with these relatively fewer number of starts. This could possibly lead to the same likelihood values from different initial starts, thus reducing the variance. A detailed investigation of this is beyond the scope of this paper but could shed further light on the properties of trust-tech-EM and other methods in high-dimensional examples.

Table 4 summarizes the average number of iterations taken by the EM algorithm for convergence to the local optimal solution. We can see that the most promising solution produced by our TRUST-TECH-EM methodology converges much faster. In other words, our method can effectively take advantage of the fact that the convergence of the EM algorithm is much faster for high-quality solutions. This is an inherent property of the EM algorithm when applied to the mixture modeling problem. We exploit this property of the EM for improving the efficiency of our algorithm. Hence, for obtaining Tier-1 solutions using our algorithm, the threshold for the number of iterations can be significantly lowered.

Using stability regions, we have a systematic approach to obtain neighboring local maxima as opposed to widely used stochastic methods (like data perturbation, annealing, mutations in genetic algorithms, etc.). These stochastic methods never guarantee the presence of a new stability region. Our algorithm not only guarantees that a new local maximum obtained is different from the original solution but also confirms that we will not miss a solution in any particular direction. Also, this algorithm provides the flexibility in choosing these directions, thus avoiding some standard problems of using EM algorithm like the boundary space problem. The standard EM algorithm might sometimes converge to the boundary of the parameter space. The boundary space problem (popularly known as the singularity problem) occurs when one of the unconstrained covariance matrices approaches zero. This can be solved by using some soft constraints over the covariance matrices. In addition to that, we can take an extra step to generate directions that will not lead the parameters of these covariances matrices toward zero. Our algorithm can be easily extended to the popularly used k-means clustering technique [20]. The proposed algorithm works not only for mixture models but also for more general nonlinear likelihood surfaces. The TRUST-TECH based EM algorithm has been successfully applied to a real-world example in bioinformatics, namely, the motif finding problem, where EM is one of the popularly used algorithms for motif refinement [26].
6 Conclusion and Future Work

A novel TRUST-TECH-based EM algorithm has been introduced for estimating the parameters of mixture models. The EM phase and the stability region phase are applied alternatively in the context of the well-studied problem of learning mixture models. The concept of a stability region helps us to understand the topology of the original log-likelihood surface. Our method computes the neighborhood local maxima of likelihood surfaces using stability regions of the corresponding nonlinear dynamical system. The algorithm has been tested successfully on various synthetic and real-world data sets and the improvements in the performance are clearly manifested.

Our algorithm can be easily extended to the popularly used k-means clustering technique. In the future, we plan to work on applying these stability-region-based methods for other widely used EM related parameter estimation problems like training Hidden Markov Models [38], Mixtures of Factor Analyzers [10], Probabilistic Principal Component Analysis [34], Bayesian Networks [13], etc. We also plan to extend our technique to MCMC strategies like Gibbs sampling for the estimation of mixture models. Constraints might be added based on some prior information about the samples and a TRUST-TECH-based constrained EM algorithm can be developed [16].
